

Both responses rise. The female-cue response stays stronger.

Recorded activity in the full-connectome model — no mating-choice rule was used.

After mAL block, the mean female-cue response was 5.5-5.6× the male-cue response.

Small circles: three fresh random seeds. Diamonds: means. Lines pair identical inputs before/after the block.

This measures modeled neural responsiveness, not the probability of choosing a mate; transmitter signs remain assumptions.

What did we change — and what did we measure?

The same network and input signal were tested twice. Only mAL output transmission changed.

What this supports

Removing an inhibitory brake can reveal a previously suppressed male-cue response.

What it does not establish

A fly choosing males over females.
Female-cue responses remained stronger.
